Abstract

In fitting dose-response models to entomological data it is often necessary to take account of natural mortality and/or overdispersion. The standard approach to handle natural mortality is to use Abbott’s formula (Abbott, 1925), which allows for a constant underlying mortality rate. Standard overdispersion models include beta-binomial models, logistic-normal, and discrete mixtures. We extend the standard model (Morgan, 1992), and include a random effect in the dose levels, using the approach described in Aitkin et al. (2009). We consider the application of this model to data from an experiment on the use of a virus (PhopGV) for the biological control of worm larvae (Phthorimaea operculella) in potatoes, using a procedure implemented in software R. Using the model with random effects in the dose levels, we obtained a better fit than that provided by the standard model.

Introduction

Models for binary and binomial response grew out of the needs of a type of experimental investigation known as bioassay. In a typical bioassay, different concentrations of a chemical compound are applied to batches of experimental subjects and the number of subjects in each batch that respond to the chemical is then recorded. These values are regarded as observations on a binomial response variable. Some experiments in entomology exhibit evidence that responses can occur even at zero dose; here the response of interest is death and this phenomenon is referred to as natural mortality.

Among the available methodologies for the analysis of data that present natural mortality, little has been developed to deal with the occurrence of both natural mortality and overdispersion. To model situations like this, one approach is to use quasi-likelihood models, for example, as used by Raymond et al. (2006) and Mascarin et al. (2010).

In a bioassay, overdispersion can occur by variation in the response probabilities for groups of insects that received the same dose level. This variation could be attributed to relevant explanatory variables that have not been recorded, or to the inclusion in the model of certain variables that have not been adequately measured or controlled. According to Collet (2002), this situation can be modelled by the inclusion of a random effect in the linear predictor and so mixed models can be used in modelling overdispersion.

The application here is to an experiment in which potatoes (Solanum tuberosum L.) were each infected with \(m_{ij} = 30\) larvae of Phthorimaea operculella, and then, \(D\) different concentrations of a virus (PhopGV) were applied to samples of \(n_i\) potatoes (observations are indexed by \(i = 1, \ldots, D\) and \(j = 1, \ldots, n_i\)). There was also a control sample (no virus, \(i = 0\)) with \(n_0 = 9\) potatoes. The experiment was conducted at 18°C, and after 60 days the numbers of dead larvae \(y_{ij}\) were counted.
Methodology

In modelling the observed proportions \( y_{ij}/m_{ij} \), the \( y_{ij} \) can be assumed to have a \( B(m_{ij}, \pi_{ij}^*) \) distribution, where \( \pi_{ij}^* \) the probability of response depends on the natural mortality and the dose-response relationship. A model for \( \pi_{ij}^* \) (Morgan, 1992) is

\[
\pi_{ij}^* = \omega_{ij} + (1 - \omega_{ij}) \pi_{ij}, \quad j = 1, \ldots, n_i \quad \text{and} \quad i = 0, \ldots, D,
\]

where \( \pi_{ij} \) is given by the tolerance distribution (normal, logistic or extreme value), and \( \omega_{ij} \) is the natural response probability. In general, we can model \( \pi_{ij} \) and \( \omega_{ij} \) as function of covariates and parameters giving the following two models:

Model (a) - Standard model

\[
\log \left( \frac{\omega_{ij}}{1 - \omega_{ij}} \right) = \gamma' u_{ij} \quad \text{and} \quad \log \left( \frac{\pi_{ij}}{1 - \pi_{ij}} \right) = \beta' x_{ij},
\]

Model (b) - Random effect in the linear predictor of the dose levels

\[
\log \left( \frac{\omega_{ij}}{1 - \omega_{ij}} \right) = \gamma' u_{ij} \quad \text{and} \quad \log \left( \frac{\pi_{ij}}{1 - \pi_{ij}} \right) = \beta' x_{ij} + \sigma Z_i,
\]

where \( Z_i \) is a random effect with standard normal distribution.

If it were possible to label the subjects who responded due to the applied dose as \( y_{ijd} \) and those who responded naturally as \( y_{ijc} \), then the total number of dead at dose \( d_{ij} \) would be

\[ y_{ij} = y_{ijc} + y_{ijd}. \]

In the control group, if the number of larvae that died is \( y_{0j} \) out of \( m_{0j} \), since they did not receive the virus we have \( y_{0j} = y_{0jc} \).

The likelihood for Models (a) and (b) is given by

\[
L(\omega_{ij}, \pi_{ij}; y_{ij}) \propto \prod_{i=1}^{D} \prod_{j=1}^{n_i} \prod_{j=1}^{m_{ij} - y_{ij}} \left[ (1 - \omega_{ij})/(1 - \pi_{ij}) \right]^{y_{ijc}} \left[ (1 - \omega_{ij}) \pi_{ij} \right]^{y_{ijd}} \omega_{ij}^{y_{ijd}} \omega_{ij}^{y_{ijc}} \times \prod_{j=1}^{m_{ij} - y_{ij}} \omega_{ij}^{y_{ijc}} \omega_{ij}^{y_{0j}} \omega_{ij}^{m_{0j} - y_{0j}}.
\]

(1)

The log likelihood of (1) for Model (a) as function of \( \beta \) and \( \gamma \) is given by

\[
l(\gamma, \beta; y) \propto \sum_{i=1}^{D} \sum_{j=1}^{n_i} \left\{ \left( m_{ij} - y_{ij} \right) \left[ \log \left( \frac{1}{1 + e^\beta' x_{ij}} \right) \right] + y_{ijd} \log \left( \frac{e^\beta' x_{ij}}{1 + e^\beta' x_{ij}} \right) \right\}
+ \left( m_{ij} - y_{ij} \right) \log \left( \frac{e^\gamma' u_{ij}}{1 + e^\gamma' u_{ij}} \right) + y_{ijd} \log \left( \frac{1}{1 + e^\gamma' u_{ij}} \right) + y_{ijc} \log \left( \frac{e^\gamma' u_{ij}}{1 + e^\gamma' u_{ij}} \right)
+ \sum_{j=1}^{m_{0j} - y_{0j}} \log \left( \frac{e^\gamma' u_{ij}}{1 + e^\gamma' u_{ij}} \right) + \left( m_{0j} - y_{0j} \right) \log \left( \frac{1}{1 + e^\gamma' u_{ij}} \right)
\]

(2)

This log-likelihood is easy to maximize, because \( l(\beta; y) + l(\gamma; y) \) can be maximized separately. The approach used to estimate the parameters was the EM algorithm (Dempster et al., 1977), as also used
in bioassays with natural mortality by Hasselblad (1980) and Barlow and Feigl (1985). With the EM algorithm, the complete log-likelihood (2) is maximized iteratively by alternating between estimating $y_{ijc}$ by its expectation under the current estimates of $\beta$ and $\gamma$ (E step) and then, with the $y_{ijc}$’s fixed at their expected values from the E step, maximizing $l(\gamma, \beta; y)$ (M-step). The $(k + 1)^{th}$ iteration of the EM algorithm for Model (a) requires three steps:

**E – Step**: Estimate $E(y_{ijc}|y_{ij})$ under the current estimates $\beta^{(k)}$ and $\gamma^{(k)}$

$$y_{ijc}^{(k)} = E(y_{ijc}|y_{ij}, \beta^{(k)}, \gamma^{(k)}) = \left\{ \begin{array}{ll} \frac{e^{\gamma^t u_{ij} y_{ij}}}{e^{\gamma^t u_{ij}} + \frac{\beta^t x_{ij}}{1 + e^{\beta^t x_{ij}}}} & \text{for } i = 1, \ldots, D; \end{array} \right.$$  

**M – Step for $\beta$**: Find $\beta^{(k+1)}$ by maximizing $l(\beta; y_{ijc}^{(k)}|y_{ij})$: $\beta^{(k+1)}$ can be found from a binomial logistic regression of the responses $y_{ijc}^{(k)} = y_{ij} - y_{ijc}$ with binomial denominator $m_{ij} - y_{ijc}$ and design matrix $X$;

**M – Step for $\gamma$**: Find $\gamma^{(k+1)}$ by maximizing $l(\gamma; y_{ijc}^{(k)}|y_{ij})$: using a binomial logistic regression of the responses $y_{ij}$ and $y_{ijc}$ with binomial denominators $m_{0j}$ and $m_{ij}$ respectively on design matrix $U$.

These three steps must be repeated until the convergence is reached. For Model (b), letting $\psi = (\gamma, \beta, \sigma)$ be the combined parameter vector, the likelihood is given by

$$L(\psi; y) = \prod_{i=0}^{D} \left\{ \int_{-\infty}^{+\infty} \left[ \prod_{j=1}^{n_i} P(y_{ij}|\psi) \right] \phi(z_i) dz_i \right\}. \tag{3}$$

The integral in the likelihood (3) does not have a closed form except for normal $Y$. For other response models it is approximated by Gaussian quadrature: the integral over the normal $Z_i$ is replaced by the finite sum over $K$ Gaussian quadrature mass points $z_k$ with masses $\alpha_k$ (Aitkin et al. 2009). The likelihood is then

$$L(\psi; y) = \prod_{i=0}^{D} \left\{ \sum_{k=1}^{K} \left[ \prod_{j=1}^{n_i} P(y_{ij}|\psi) \right] \alpha_k \right\},$$

where $P(y_{ij}|\psi) = \left( \frac{m_{ij}}{y_{ij}} \right)^{y_{ij}} \left( 1 - \frac{m_{ij}}{y_{ij}} \right)^{m_{ij} - y_{ij}}$.

The likelihood is thus (approximately) the likelihood of a finite mixture of exponential families density with known mixture proportions $\alpha_k$ at known mass-points $z_k$, thus $z_k$ becomes another observable variable in the regression, with regression coefficient $\sigma$.

The log-likelihood is $l(\psi; y) = \sum_{i=0}^{D} \log \left( \sum_{k=1}^{K} \alpha_k \rho_{ik} \right)$, with $\rho_{ik} = \prod_{j=1}^{n_i} P(y_{ij}|\psi)$.

Then

$$\frac{\partial l}{\partial \beta} = \sum_{i=0}^{D} \sum_{k=1}^{K} \alpha_k \rho_{ik} \frac{\partial \log \rho_{ik}}{\partial \beta} = \sum_{i=0}^{D} \sum_{j=1}^{n_i} \sum_{k=1}^{K} w_{ik} s_{ijk}(\beta),$$

where $w_{ik}$ is the posterior probability that observation $y_{ij}$ comes from component $k$,

$$w_{ik} = \frac{\alpha_k \rho_{ik}}{\sum_{l=1}^{K} \rho_{il}}$$

and $s_{ijk}(\beta)$ is the $\beta$-component of the score function for observation $(ij)$ in component $k$,

$$s_{ijk}(\beta) = \frac{(y_{ij} - \mu_{ijk}) x_{ij}}{\left( \frac{m_i \mu - \mu^2}{m_i} \right) g_{ijk}^2}.$$
Following Anderson and Hinde (1988), the estimate of $\sigma$ can be found by regarding $Z_i$ as an additional covariate and $\sigma$ as an extra parameter in the linear predictor. Estimation proceeds by fitting a weighted generalized linear model using $w_{ik}$ as additional weights. These weights are functions of $Z_i$, $Y_i$, $\sigma$ and $\beta$ and must themselves be estimated iteratively.

The steps of the EM algorithm for model (b) are the following:

**E – Step**: Estimate $E(y_{ijc} \mid y_{ij})$ under the current estimates $\beta^{(k)}$, $\sigma^{(k)}$ and $\gamma^{(k)}$,

$$y_{ijc}^{(k)} = E(y_{ijc} \mid y_{ij}, \beta^{(k)}, \sigma^{(k)}, \gamma^{(k)}) = \begin{cases} \frac{e^{u_{ij}y_{ij}}}{1+e^{u_{ij}y_{ij}+\beta'z_{ij}+\sigma_i}} & \text{for } i = 1, ..., D. \end{cases}$$

**M – Step** for $\beta$ and $\sigma$: Find $\beta^{(k+1)}$ and $\sigma^{(k+1)}$ by maximizing $l(\beta, \sigma; y_{ijc} \mid y_{ij})$, $\beta^{(k+1)}$ and $\sigma^{(k+1)}$ can be found from a weighted binomial regression of the responses $y_{ijc}^{(k)} = y_{ij} - y_{ijc}^{(k)}$ with binomial denominator $m_{ij} - y_{ijc}^{(k)}$ with weights $w_{ik}$ for a design matrix $X$ augmented by a vector $z$ of the $k$ Gaussian quadrature points.

**M – Step** for $\gamma$: Find $\gamma^{(k+1)}$ by maximizing $l(\gamma; y_{ijc} \mid y_{ij})$: using a binomial logistic regression of the responses $y_{ij}$ and $y_{ijc}^{(k)}$ with binomial denominators $m_{0j}$ and $m_{ij}$ respectively on design matrix $U$.

In model (b) 20 quadrature points were used and the procedures were implemented in the R package.

**Main Results and Conclusions**

We included random effects in the standard model for natural mortality in the dose levels, with the aim to provide a better fit when the dataset exhibits overdispersion.

For the comparison between models, we also fitted a standard binomial model (Model (c)), with link functions logit and complementary log-log, without taking into account the natural mortality. Table 2 presents the fit statistics ($-2 \log$ likelihood, AIC and BIC) for models (a), (b) and (c).

For these three statistics, the smaller the value the better is the fit. In Figure 1 we plot models (a), (b) and (c) with the link function logit, and in Figure 2 we plot models (a), (b) and (c) with the link function complementary log-log.

The fitted values for the models (b) were obtained by the empirical Bayes predictions (Aitkin, 1996). The effective dose $ED_{100p\%}$ values, are doses which correspond under the model to 100$p\%$ mortality.

A commonly used summary of a fitted model is the $ED_{50}$, the dose corresponding to 50$\%$ mortality, that has a useful interpretation as the median of the tolerance distribution. In Table 2 are the values of the $ED_{50}$ in log scale for the fitted models. For models (b), the approach used to calculate de $ED_{50}$ is described in Gutreuter and Boogaard (2007).

With the inclusion of the random effect in the dose levels, the effective dose for the logistic model is 4.57 and for the complementary log-log model is 4.86. The $ED_{50}$ when the natural mortality is not taken into account is underestimated, and when natural mortality is taken into account, but without random effect, the $ED_{50}$ is overestimated, compared to the logist model with random effect that provides the best fit. We concluded that data from biological assays that present natural mortality
and overdispersion can be more realistically modelled when a random effect is included to account for variability among the potatoes that received the same dose levels. For this dataset, the model with random effect in the linear predictor in the dose levels and logit link provides a better fit, and this model has response probability equation given by

\[ \hat{\pi}_{ij} = 0.32 + (0.68) \frac{\exp[-7.61 + 1.66 \log_{10}(d_{ij}) + 0.74 z_i]}{1 + \exp[-7.61 + 1.66 \log_{10}(d_{ij}) + 0.74 z_i]} . \]
