Seismic Rayleigh waves on an exponentially graded, orthotropic half-space

Michel Destrade

2006

Abstract

Efforts at modelling the propagation of seismic waves in half-spaces with continuously varying properties have been mostly focused on shear-horizontal waves. Here a sagittaly polarized (Rayleigh type) wave travels along a symmetry axis (and is attenuated along another) of an orthotropic material with stiffnesses and mass density varying in the same exponential manner with depth. Contrary to what could be expected at first sight, the analysis is very similar to that of the homogeneous half-space, with the main and capital difference that the Rayleigh wave is now dispersive. The results are illustrated numerically for (i) an orthotropic half-space typical of horizontally layered and vertically fractured shales and (ii) for an isotropic half-space made of silica. In both examples, the wave travels at a slower speed and penetrates deeper than in the homogeneous case; in the second example, the inhomogeneity can force the wave amplitude to oscillate as well as decay with depth, in marked contrast with the homogeneous isotropic general case.

1 Introduction

Love (1911) showed that a inhomogeneous half-space, consisting of an elastic layer covering a semi-infinite body made of a different elastic material, can sustain the propagation of a linearly polarized (shear horizontal) surface wave. The Love wave is faster than the elliptically polarized (vertical) Rayleigh (1885) wave and it has been observed countless times during earthquakes or underground explosions. Another recorded phenomenon is that Rayleigh waves are dispersive, a characteristic which is incompatible with the context of a homogeneous half-space given by Rayleigh (1885): Love showed
that his layer/substrate configuration could also support a two-partial, vertically polarized, surface wave. Because this configuration introduces a new characteristic length, the layer thickness $h$ (say), a dispersion parameter is now $kh$ where $k$ is the wave number, and that surface wave is dispersive.

Subsequent analyses introduced more and more layers to refine the model, until it was considered practical to view the inhomogeneity of the half-space as a continuous variation of the material properties (Ewing et al. 1957). Chief among these continuous variations is the one for which the elastic stiffnesses and the mass density vary exponentially with depth, all in the same manner, proportional to a common factor $\exp(-2\alpha x_2)$ say, where $\alpha$ is the inverse of a inhomogeneity characteristic length, and $x_2$ is the coordinate along the normal to the free surface, so that here a dispersion parameter is now $\alpha/k$ for instance. Hence Wilson (1942), Deresiewicz (1962), Dutta (1963), Bhattacharya (1970), and many others studied the propagation of surface waves in such inhomogeneous media; they were however interested in shear-horizontal waves (Love-type). The literature on Rayleigh-type surface waves in that type of media is quite scarce, probably because the difficulty exposed below is encountered quite early in the analysis.

In an anisotropic elastic body with continuously variable properties, the general equations of motion read

$$C_{ijkl}u_{l,kl} + C_{ijkl,j}u_{l,k} = \rho u_{i,tt},$$

where $u$ is the mechanical displacement, and $C_{ijkl}$ and $\rho$ are the elastic stiffnesses and the mass density, respectively. Now consider the propagation of an inhomogeneous plane wave with speed $v$ and wave number $k$ in the $x_1$-direction, and with attenuation in the $x_2$-direction,

$$u = U^o e^{ik(x_1+qx_2-\omega t)},$$

in a half-space $x_2 \geq 0$ made of an orthotropic\footnote{An anisotropic material belongs to the orthotropic symmetry class when it possesses three mutually orthogonal planes of mirror symmetry.} material with an exponential depth profile,

$$\{c_{11}(x_2), c_{22}(x_2), c_{12}(x_2), c_{66}(x_2), \rho(x_2)\} = e^{-2\alpha x_2}\{c^\circ_{11}, c^\circ_{22}, c^\circ_{12}, c^\circ_{66}, \rho^\circ\}. \tag{3}$$

Here the $x_1$, $x_2$, $x_3$ directions are aligned with the axes of symmetry, $\alpha$ is a real number, and the $c_{ij}$ and $\rho^\circ$ are constants; also, $U^o$ is a constant vector and $q$ a complex number so that the attenuation factor is $k\Im(q)$. Then the equations of motion \footnote{\cite{1}} yield

$$\begin{bmatrix} c_{66}^\circ q^2 + c_{11}^\circ - \rho v^2 + 2i(\alpha/k)qc_{66}^\circ & q(c_{12}^\circ + c_{66}^\circ) + 2i(\alpha/k)c_{66}^\circ \\ q(c_{12}^\circ + c_{66}^\circ) + 2i(\alpha/k)c_{12}^\circ & c_{22}^\circ q^2 + c_{66}^\circ - \rho v^2 + 2i(\alpha/k)qc_{22}^\circ \end{bmatrix} U^o = 0. \tag{4}$$
At $\alpha = 0$, the material is homogeneous, and the associated determinantal equation – the propagation condition – is a real quadratic in $q^2$ which can be solved exactly (Sveklo, 1948).

At $\alpha \neq 0$, the propagation condition is seemingly a quartic in $q$ with complex coefficients, whose analytical resolution might appear to be a daunting task and to preclude further progress toward the completion of a boundary value problem (note that it remains a quartic even when the material is isotropic.) Hence, Das et al. (1992) and Pal & Acharya (1998) stopped their analytical study of that problem at that very point. In fact the transformation of the quartic to its canonical form reveals that it is a quadratic in $q + i(\alpha/k)$, with real coefficients. That this is so has rarely been identified: Biot (1965), in the context of incremental static deformations, seems to be the only one who has recognized this simplification. The present paper shows that the Stroh (1962) formulation of this problem, combined with a change of unknown functions, leads naturally to the biquadratic in question. Then the propagation condition can be solved exactly, and the general solution of form (2) to the equations of motion follows. In particular, the resolution of the dispersive Rayleigh wave boundary value problem poses no particular difficulty after all. Section 2 exposes this analysis, and Section 3 applies it to two types of exponentially graded half-spaces: one which would be made of orthotropic shales if $\alpha \to 0$ and another which would be made of silica (isotropic). There, it is seen for both examples that the influence of the inhomogeneity is more marked upon the wave speed (rapidly decreasing with $\alpha/k$) than upon the attenuation factors (slowing increasing with $\alpha/k$). It is also found that the attenuation factors for the displacement amplitudes are distinct from those for the traction amplitudes, and that the amplitudes can decay in an oscillating manner for the isotropic silica. These two features are unusual and are clearly due to the inhomogeneity.

The overall aim of the paper is to show that simple, analytical, exact results can be obtained for seismic Rayleigh wave propagation in an anisotropic, inhomogeneous Earth. Of course it is unlikely any “real” inhomogeneity can be such that the stiffnesses and the mass density all vary in the same manner as in (3), because it then leads to bulk wave speeds (proportional to the square root of stiffnesses divided by the density) which are constant with depth. The analysis of more realistic models must turn to numerical simulations such as those based on the finite difference technique or on the pseudospectral technique or on techniques with Fourier or other function expansions (e.g. Tessmer 1995). These methods however encounter difficulties for the implementation of accurate boundary conditions and of strong heterogeneity. The spectral element method seem to alleviate those difficulties but, as stressed by Komatitsch & al. (2000), it must be validated against
analytical solutions. Such a solution validation procedure is indeed a crucial necessity of numerical simulations in geophysics, where different software packages can give widely different predictions (Hatton 1997).

2 The dispersion equation

Consider the propagation of a Rayleigh wave, traveling with speed $v$ and wave number $k$ in the $x_1$-direction, in an inhomogeneous half-space $x_2 \geq 0$ made of the orthotropic material presented in the Introduction. The associated mechanical quantities are the displacement components $u_j$ and the traction components $\sigma_{j2}$ ($j = 1, 2$). They are now taken in the form

$$\{u_j, \sigma_{j2}\}(x_1, x_2, t) = \{U_j(x_2), i\tau_{j2}(x_2)\} e^{ik(x_1-vt)}, \quad (5)$$

where the $U_j$, $\tau_{j2}$ ($j = 1, 2$) are yet unknown functions of $x_2$ alone, to be determined from the equations of motion and from the boundary conditions.

The equations of motion: $\sigma_{ij,j} = \rho u_{i,tt}$, can be written as the second-order differential system (1), or as the following first-order differential system,

$$\begin{bmatrix} U' \\ t' \end{bmatrix} = i \begin{bmatrix} kN_1 \\ \frac{k^2e^{-2\alpha x_2}K}{kN_1} \end{bmatrix} \begin{bmatrix} U \\ t \end{bmatrix}. \quad (6)$$

Here $N_1, N_2, K$ are the usual constant matrices of Stroh (1962), given by

$$N_1 = \begin{bmatrix} 0 & -1 \\ -c_{12}^0 & 0 \end{bmatrix}, \quad N_2 = \begin{bmatrix} 1 \\ c_6^0 \\ 0 \end{bmatrix}, \quad K = \begin{bmatrix} X - c^0 & 0 \\ 0 & X \end{bmatrix}. \quad (7)$$

where $c^0 := c_{11}^0 - \frac{c_{12}^2}{c_{22}^0}$ and $X := \rho^0 v^2$. With the new vector function $\xi$, defined as

$$\xi(x_2) := [e^{-\alpha x_2}U(x_2), e^{\alpha x_2}t(x_2)]^t, \quad (8)$$

the system (6) becomes

$$\xi' = iK\xi \quad \text{where} \quad N := \begin{bmatrix} N_1 + i(\alpha/k)I & (1/k)N_2 \\ kK & N_1 - i(\alpha/k)I \end{bmatrix}. \quad (9)$$

Hence the apparently anodyne change of unknown functions (8) transforms the differential system with variable coefficients (6) into one with constant coefficients.
Now solve the differential system (9) with a solution in exponential evanescent form,
\[ \xi(x_2) = e^{ikpx_2} \zeta, \quad \Im(p) > |\alpha|/k, \]  
(10)
where \( \zeta \) is a constant vector, \( p \) is a scalar, and the inequality ensures that
\[ u(\infty) = 0, \quad t(\infty) = 0, \quad \xi(\infty) = 0, \]  
(11)
because by (8) and (10), \( u(x_2) \) behaves as: \( \exp k(ip + \alpha/k)x_2 \) and \( t(x_2) \) behaves as: \( \exp k(ip - \alpha/k)x_2 \). Note in passing that, in sharp contrast to the homogeneous case, the displacement field and the traction field have different attenuation factors: for \( u \) it is \( k[\Im(p) - \alpha/k] \); for \( t \) it is \( k[\Im(p) + \alpha/k] \).

Then \( \zeta \) and \( p \) are solutions to the eigenvalue problem:
\[ N\zeta = p\zeta. \]  
The associated determinantal equation is the propagation condition, here a bi-quadratic (and not a quartic as Eq.(4) suggested),
\[ p^4 - Sp^2 + P = 0, \]  
(12)
where
\[ S = [c_{12}^6 + 2c_{12}^6c_{66} - c_{11}^0c_{22} + (c_{22}^0 + c_{66}^0)X]/(c_{22}^0c_{66}^0) - 2(\alpha/k)^2, \]
\[ P = (c_{11}^0 - X)(c_{66}^0 - X)/(c_{22}^0c_{66}^0) - (\alpha/k)^2[c_{12}^2 - 2c_{12}^2c_{66} - c_{11}^0c_{22} + (c_{22}^0 + c_{66}^0)X]/(c_{22}^0c_{66}^0) + (\alpha/k)^4. \]  
(13)
Let \( p_1 \) and \( p_2 \) be the two roots of (12) satisfying inequality (10). That pair may be in one of the two forms: \( p_1 = ib_1, p_2 = ib_2 \), or \( p_1 = -a + ib, p_2 = a + ib \), where \( b, b_1, b_2 \) are positive. In both cases, \( p_1p_2 \) is a real negative number and \( p_1 + p_2 \) is a purely imaginary number with positive imaginary part. It follows in turn that
\[ p_1p_2 = -\sqrt{p_1^2p_2^2} = -\sqrt{P}, \quad p_1 + p_2 = i\sqrt{-(p_1 + p_2)^2} = i\sqrt{2\sqrt{P} - S}. \]  
(14)
The associated eigenvectors \( \zeta^1, \zeta^2 \) are determined from: \( N\zeta^j = p_j\zeta^j, \) as
\[ \zeta^j = \begin{bmatrix} p_j^2 + 2i(\alpha/k)p_j - e_0 \\
[p_j^3 + i(\alpha/k)p_j + f_1p_j + i(\alpha/k)f_0] \\
-k[g_1p_j + i(\alpha/k)g_0] \\
-k[Xp_j^2 + h_0] \end{bmatrix}, \]  
(15)
where the non-dimensional quantities $e_0, f_1, f_0$ appearing in the displacement components are given by
\[
e_0 = (\alpha/k)^2 + c_{12}^0 (c_{66}^0 - X)/(c_{22}^0 c_{66}^0),
\]
\[
f_1 = (\alpha/k)^2 + (c^0 - X)/c_{66}^0 - c_{12}^0/c_{22}^0,
\]
\[
f_0 = (\alpha/k)^2 + (c^0 - X)/c_{66}^0 + c_{12}^0/c_{22}^0,
\]
and the quantities $g_1, g_0, h_0$ (dimensions of a stiffness) appearing in the traction components are given by
\[
g_1 = c^0 - (1 + c_{12}^0/c_{22}^0)X,
\]
\[
g_0 = c^0 - (1 - c_{12}^0/c_{22}^0)X,
\]
\[
h_0 = (\alpha/k)^2 X - (c^0 - X)(c_{66}^0 - X)/c_{66}^0.
\]
Now construct the general solution to the equations of motion (9) as
\[
\xi(x_2) = \gamma_1 e^{ikp_1x_2} \zeta^1 + \gamma_2 e^{ikp_2x_2} \zeta^2,
\]
where the constants $\gamma_1, \gamma_2$ are such that the surface $x_2 = 0$ is free of tractions: $t(0) = 0$ or equivalently: $\xi(0) = [U(0), 0]^t$. This condition leads to a homogeneous linear system of two equations for the two constants, whose determinant must be zero. After factorization and use of (14), the dispersion equation follows as
\[
g_1(X\sqrt{P} + h_0) + (\alpha/k)g_0 X\sqrt{2\sqrt{P} - S} = 0. \tag{19}
\]
This equation is fully explicit ($X$ is the sole unknown) because $P$ and $S$ are given in (13) and $g_1, g_0, h_0$ are given in (17), and it is clearly dispersive due to the multiple appearance of the dispersion parameter $\alpha/k$. At $\alpha = 0$ (homogeneous substrate), it simplifies to
\[
X\sqrt{(c_{11}^0 - X)(c_{66}^0 - X)/c_{22}^0 c_{66}^0} - (c^0 - X)(c_{66}^0 - X)/c_{66}^0 = 0, \tag{20}
\]
the classic (non-dispersive) secular equation for Rayleigh waves in orthotropic solids.

3 Examples: exponentially graded shales and silica

As two examples of application, consider in turn that the half-space is made of a material with exponentially variable properties which is (i) with orthotropic symmetry and (ii) isotropic.
In Example (i) the starting point is a model proposed by Schoenberg and Helbig (1997), accounting for the vertical fine stratification and the vertical fractures found in many shales. In their numerical simulations, they used the following orthotropic elastic stiffness matrix,

\[
\begin{bmatrix}
9 & 3.6 & 2.25 & 0 & 0 & 0 \\
3.6 & 9.89 & 2.4 & 0 & 0 & 0 \\
2.25 & 2.4 & 5.9375 & 0 & 0 & 0 \\
0 & 0 & 0 & 2 & 0 & 0 \\
0 & 0 & 0 & 1.6 & 0 & \frac{1}{2} \\
0 & 0 & 0 & 0 & 2.182 & \frac{1}{2}
\end{bmatrix}
\]  

(21)

Note that here the matrix is density-normalized so that its components have the dimensions of squared speeds, expressed in \((\text{km/s})^2\) (Schoenberg 1994). Schoenberg and Helbig remark that “the rock mass behaves as if it contains systems of parallel fractures increasing the compliance in some directions”; integrating this information, \(\alpha\) is assumed positive here. Also, (21) is assumed to be the elastic stiffness matrix on the free surface \(x_2 = 0\).

In Example (ii), the half-space is assumed to be made of an exponentially graded material such that at the boundary, \(c_{11}^o = 7.85\), \(c_{12}^o = 1.61 \times 10^{10} \text{ N/m}^2\) and \(\rho^o = 2203 \text{ kg/m}^3\) as in silica (Royer & Dieulesaint 2000). Here too, \(\alpha\) is taken positive.

If the half-spaces were homogeneous, then the Rayleigh wave would travel with speed \(v^o = \sqrt{X/\rho^o}\) where \(X\) is given by (20), that is \(v^o = 1.412 \text{ km/s}\) for shales and \(v^o = 3409 \text{ m/s}\) for silica. For any given dispersion parameter \(\alpha/k\), the dispersion equation (19) in the inhomogeneous half-spaces gives a unique root \(X\). In both examples, it has then been checked that for that \(X\), the propagation condition (12) gives two roots such that the inequality (10) is always satisfied. Thus the surface wave exists for arbitrary value of \(\alpha/k\), and it travels with speed \(v = \sqrt{X/\rho^o}\). Although this state of affair is acceptable mathematically, it seems reasonable to limit the range of \(\alpha/k\) to values where the wave amplitude decays faster than the inhomogeneity. Because the amplitudes of the tractions \(t\) decay as \(\exp(-k[\Im(p) + \alpha/k])\), they always decrease faster than \(\exp(-2\alpha x_2)\) by (10)\(2\); on the other hand, the amplitudes of the displacements \(u\) decay as \(\exp(-k[\Im(p) - \alpha/k])\); thus they decrease faster than the inhomogeneity as long as \(\Im(p) > 3\alpha/k\). In Example (i), it turns out that this latter inequality is verified for \(\alpha/k < 0.107\), and in Example (ii), for \(\alpha/k < 0.274\).

Fig. 1 shows the variation of the wave speed (decreasing) and of \(\Im(p_1)\), \(\Im(p_2)\) (increasing) in Example (i) over the range \(0 \leq \alpha/k \leq 0.1\). It has also been checked there that the attenuation factors for both the displacements amplitudes \((k[\Im(p) - \alpha/k])\) and the tractions amplitudes \((k[\Im(p) - \alpha/k])\)
increase also. In conclusion, the surface wave travels at a slower speed in the inhomogeneous shales than in the homogeneous shales, and it is less localized.

Fig. 2 shows the variation of the wave speed (decreasing) and of $\Im(p_1)$, $\Im(p_2)$ (increasing) in Example(ii) over the range $0 \leq \alpha/k \leq 0.25$. It has been checked again that the attenuation factors for both the displacements amplitudes ($k[\Im(p) - \alpha/k]$) and the tractions amplitudes ($k[\Im(p) - \alpha/k]$) increase also. Here again, the surface wave travels at a noticeably slower speed in the inhomogeneous case than in the homogeneous case, and it is slightly less localized. A most interesting phenomenon occurs at $\alpha/k \approx 0.211$ where the nature of the roots changes from the form: $p_1 = ib_1$, $p_2 = ib_2$, to the form: $p_1 = -a+ib$, $p_2 = a+ib$, so that the amplitudes switch from decaying in a real exponential manner to decaying in an exponential oscillating manner. This latter situation never arises in a homogeneous isotropic half-space.
