20   Running head: intertidal landscape effects

21

22   Pre-print version

25 **ABSTRACT**

26 **Aim** We tested whether the size of habitat patches along the coastline of Great Britain

27 influences molluscan species richness.

28

29 **Location** Coastline of Great Britain.

30

31 **Methods** Intertidal mollusc data were compiled from the National Biodiversity Network to

32 derive a matrix of species presence/absence in 10 km × 10 km squares (hectads). Major

33 groupings within the coastal fauna were identified using clustering based on Simpson's

34 dissimilarity index. Contiguous hectads assigned to the same cluster were considered as

35 patches. Potential island biogeographical effects were investigated using regressions of

36 species density against patch size.

37

38 **Results** 598 hectads were clustered into 15 groups, with the three largest groups (94% of

39 hectads) having broad associations consistent with hectad dominance by rocky shore habitat,

40 sheltered sediment or sediment on exposed coasts. For all three main groups, there were

41 fewer species in larger patches than would be expected from a random sampling of hectads.

42 Species densities (species hectad^{-1}) increased with patch size in rocky shore-dominated

43 habitat. There was no support for a similar effect in sedimentary habitats, with higher than

44 expected species richness in isolated hectads of sheltered habitat.

45

46 **Main conclusions**

47 The increases in mollusc species density with patch size in rocky shore dominated habitat are

48 consistent with island biogeographical processes. The absence of similar effects in

49 sedimentary habitats may reflect more overlap between the species of intertidal and subtidal

50 in these habitats. Subtidal habitat may therefore act to change the hostility of the matrix

51 between intertidal patches of sedimentary habitat, diluting any island effects. As landscape

52 effects may change species richness at the scale examined, concerns that increased building

53 of artificial habitats will change the local patterns of species richness may be justified for

54 rocky habitats.

58 area, species richness

INTRODUCTION

Several different processes may cause variation in the species richness of differently sized patches of habitat. Larger segments of habitat may have greater species richness than smaller areas of similar habitat as a consequence of holding more individuals (Preston, 1962). Larger patches of habitat may also be associated with higher species richness as the increased area samples a greater amount of environmental heterogeneity (Stein *et al.*, 2014). If the number of species in comparable areas (e.g., same-size plots) within small patches and large patches differs, this requires further explanation (Fahrig, 2013). One of the most widely known explanations for an increase in species density (species per unit area) in larger fragments is the theory of island biogeography (MacArthur & Wilson, 1967): larger islands have lower extinction rates and/or higher species immigration rates than smaller islands, resulting in more species at the equilibrium point between species extinction and species immigration. Island biogeography has often been applied to habitat mosaics, where the matrix is not as hostile as the sea is to inhabitants of true islands. Matrix effects can alter island biogeographical processes by obscuring patterns of habitat specialists (Cook *et al.*, 2006). The edge of habitat fragments can be areas of increased richness as 'mass effects' allow species to persist in unfavourable habitats due to immigration from an adjacent favourable matrix (Kunin, 1998). Positive or negative edge effects may arise from altered or intermediate habitats around the perimeter of patches (Ewers & Didham, 2006).

Despite the wealth of theory related to patch, island and landscape effects, it is not always clear how the different potential processes may be evident in different systems. This of course reflects both scale-dependent differences across studies, variations in species traits such as dispersal capacity and differences in the composition and heterogeneity of landscapes (Sólymos & Lele, 2012). Studies of landscape effects in marine systems lag behind the

84   terrestrial literature (Boström *et al.*, 2011), and yet there are many concerns about changes in

85   marine habitats due to sea level rise, habitat loss and habitat modification (e.g., Bulleri &

86   Chapman 2010; Jackson & McIlvenny, 2011; Hawkins, 2012). Landscape effects on species

87   richness (e.g., Steffan-Dewenter, 2003) have implications for managing habitat change and

88   conservation planning.

89

90   To investigate how intertidal species richness may be linked to landscape structure we used a

91   clustering approach to identify the broad-scale structure of intertidal molluscan diversity

92   around Great Britain. Structure was defined at the grain scale of 10 km × 10 km squares

93   (hectads). Having identified a parsimonious description of heterogeneity at the hectad scale,

94   the links between patch size (based on neighbouring hectads of the same cluster) and species

95   richness were examined using null models (Gotelli, 2001). Null models, in the current study

96   as random selections of hectads into patches, can be used to generate an expectation for

97   patches in the absence of spatial structuring processes. For example, if there are Allee effects

98   (Gascoigne & Lipcius, 2004) or colonization–extinction dynamics that require local (within

99   patch) population sources, then larger patches may have more persistent populations and

100   higher species richness as envisioned by MacArthur & Wilson (1967). If edge or isolation

101   effects restrict the colonization and persistence of populations in small patches, then there

102   should be fewer species than expected in small groups of hectads.

103

104   The observed diversity of patches of habitat will be influenced by a number of processes.

105   Ideally these could be controlled by a standardized sampling programme, but it is not feasible

106   to generate contiguous coverage along extensive coastlines using such an approach. The

107   patterns of diversity in habitat patches were therefore examined using a proxy for collection

108   effort. An indented coastline may also reflect greater intertidal area or habitat heterogeneity,

109   for example by creating variance in wave exposure. This proxy was also examined using

110   coastline length as a possible influence on species richness. Considering the two additional

111   predictor variables led to a more robust test of the central question: whether species density

112   increased in larger patches of intertidal habitat. This was supplemented by a test of species

113   accumulation to test whether total species richness in patches was greater or lesser than

114   expected by chance selection of hectads.

115

116   **MATERIALS AND METHODS**

117   **Broad scale habitat structure**

118   Existing shoreline maps (Fig. 1) were used to help identify likely habitat associations of

119   clusters identified separately using species presence–absence in hectads. The available

120   shoreline maps are based on digitized coastlines, cross-referenced with satellite images;

121   http://www.eurosion.org. One of the major habitat distinctions is between sedimentary shores

122   (beaches) and rocky shores. The Eurosion categories emphasize a further group of habitats

123   generally found in estuaries. The category of 'conglomerates and/or cliffs with rock and

124   sediment on shore' is intermediate between sedimentary and rocky shores. The match to rock

125   or sediment dominance for the conglomerates category is dependent on local factors.

126

127   **Clustering of species assemblages**

128   Species presence records in 10 km × 10 km hectads in the UK National grid system were

129   extracted from the National Biodiversity Network (NBN; http://data.nbn.org.uk; records

130   accessed 19/11/2008). The data were examined to remove ambiguous records (e.g., those

131   with genus name only) and filtered to include intertidal records only, as described in Blight *et*

132   *al.* (2009). Molluscs were used as a suitable indicator phylum for distributional patterns as

133   this group is relatively widely collected and identified, occurs in both hard and soft shore

134   habitats and has been found to act as a surrogate for other littoral species (Smith, 2005).

135   Species authorities follow the World Register of Marine Species (WoRMS Editorial Board,

136   2015).

137

138   There were 598 hectads with data on mollusc presence. It is not possible to extrapolate the

139   existing habitat classification for the UK intertidal (JNCC biotopes, Connor *et al.*, 2004) to

140   hectads as this would require a greater coverage of biotope maps than currently exists and

141   additional decisions on how to deal with mixtures of biotopes at the 10 km $\times$ 10 km grain size

142   of the available species data. Clustering was therefore applied directly to the matrix of

143   species records to define groups of hectads with similar species (Kreft & Jetz, 2010).

144   Dissimilarities between hectads were calculated using Simpson's dissimilarity index (β_{sim},

145   Koleff *et al.*, 2003). The advantage of Simpson's index in this context is that it summarizes

146   information on the turnover element of beta diversity (Baselga, 2010). In cases such as the

147   NBN data, where details of collection effort are variable and often unknown, a reduced

148   species list for a hectad is more likely to represent under-collection than an absence of

149   species. We are interested in fairly broad habitat classifications so that, on balance, a hectad

150   with just the most common species for, say, rocky shores will cluster with a hectad with a

151   longer species list containing the same common species. In such cases, Simpson's index is

152   preferable to other common indices like Sørensen's, which are also influenced by the change

153   in species number, even if all species in the species-poor hectad are also found in the species-

154   rich area.

155

156   The matrix of Simpson's dissimilarities among hectads was clustered using average

157   dissimilarities among groups (UPMGA) using the HCLUST package in R (R Development

158   Core Team, 2013). A stopping rule is needed to judge the number of clusters that represents a

159 parsimonious description of structure in the data. Methods for finding an 'elbow' in cluster

160 dispersion data (Kreft & Jetz, 2010) did not work satisfactorily in this study: the decline in

161 within-cluster dispersion with group number was too smooth. We attempted to find a cluster

162 number using a technique based on resampling the locations to create a null expectation of

163 cluster structure (cf. Dudoit & Fridlyand, 2002). A conventional r^2 statistic was used to judge

164 the degree to which clusters represent the distances between hectads. The squared distances

165 from cluster centroids required to calculate r^2 can be obtained from the sum of squared

166 distances between cluster members divided by the number of sites in the cluster (Anderson &

167 Thompson, 2004). The expectation is that r^2 will rise more or less asymptotically to 1 as the

168 number of clusters approaches the number of hectads. This will occur even as hectads are

169 randomly assigned to clusters of the same size as those defined from hierarchical clustering.

170 The difference between the r^2 from hierarchical clusters defined by group averaging and

171 clusters assembled randomly gives an estimate of the degree of structure for any given

172 number of groups. To estimate the expectation from random allocation of hectads to clusters,

173 the average r^2 was calculated after 100 randomizations for each node in the hierarchical

174 clustering using the 'sample' command in R to reallocate cluster membership.

175

176 **Patch size effects**

177 By defining an informative clustering of hectads, the spatial structure within cluster groups

178 could be examined. Hectads from the same cluster group were considered to form patches

179 when they were contiguous (using an eight cell neighbourhood). For the most common

180 clusters, this led to a relatively large number of fragments (patches), separated by areas of

181 different habitat. The number of hectads of the same cluster in each patch defines the patch

182 size hereafter.

183

184   In any heterogeneous system, species richness will increase with an increasing sample area or

185   number of independent sample quadrats, reflecting the increased effort. The term species

186   accumulation is used to refer to this effect (Gotelli & Colwell, 2001). We therefore expect

187   overall species richness to be linked to patch size. An appropriate null model of species

188   accumulation is needed to test for the presence of additional influences on species richness in

189   patches. A null model for the expected rate of increase of species in the absence of spatial

190   structure can be estimated from a random resampling process. Hectads within each habitat

191   group were randomly reassigned to patches to generate a species accumulation in the absence

192   of any island biogeographical effects. Simulations were carried out using POPTOOLS (Hood,

193   2010). The size of any observed departure from the null expectation was expressed using z-

194   scores, the difference between observed and mean resampled species number for each patch

195   divided by the SD from 100 randomizations. Extended tests indicated that the null

196   expectations were stable at 100 simulations and larger resampling trials were not needed. If

197   there are no patch effects, then the z-scores should lie close to zero with no trend associated

198   with changes in patch size.

199

200   An alternative means of examining the patch size effect is to test the average number of

201   species for a fixed area in different sized fragments (Fahrig, 2013; called D-SAR in Giladi *et*

202   *al.*, 2014). This was tested using regressions of the mean species richness hectad^{-1} in patches,

203   as a function of the patch size for different habitats. If patch-related processes help species

204   establish or persist at the hectad scale, then the regression of mean hectad richness should

205   have a positive slope.

206

207   Alongside any landscape effects at the patch scale, two alternative predictors were also

208   examined to evaluate other potential influences on average richness hectad^{-1} in patches. The

209 collection effort in the NBN database is uneven as the data reflect the amalgamation of

210 different surveys. Details like the number of individuals examined or survey effort in

211 different contributions to the NBN data are generally not known. Blight *et al.* (2009) found

212 that the number of survey records in a hectad helped explain variation in species richness.

213 'Survey records' in this context includes repeat observations of the same species so that data

214 of this sort includes information on the total effort expended in the hectad. A further variable

215 that may influence species richness in patches of hectads is the length of coastline found there.

216 A heactad containing a relatively longer fragment of coastline may contribute more species to

217 a patch if a longer coastline implies a more convoluted shoreline where habitat heterogeneity

218 results in increased species richness. A longer coastline also implies a greater intertidal area

219 within a hectad. Greater area within a hectad may also boost species richness if island

220 biogeographical processes operate at this scale. The average coastline length per hectad

221 within a patch was therefore examined as a third potential predictor of patch species richness.

222

223 **Analysis of patch effects**

224 The species accumulation (z-scores) relationships with patch size were examined using

225 ANCOVA with group as a fixed factor and patch size as the covariate. Residual plots were

226 examined for departures from normality and homoscedasticity and these assumptions were

227 supported by the diagnostic plots. Full ANCOVA models (including the group $\times$ patch size

228 interaction term) were fitted and compared with models containing the main effects only. The

229 optimum model to descried the data was subsequently chosen on the basis of the lowest small

230 sample corrected Akaike Information Coefficient (AIC_c). Akaike weights were used to

231 compare candidate models. The Akaike weight indicates the relative support for a model,

232 while the ratio between the weights of different models (the evidence ratio) indicates the

233   likelihood that one model is a better fit to the data than the comparator (Burnham and

234   Anderson, 2002).

235

236   Calculating the mean species hectad^{-1} involved estimates with varying precision (dependant

237   on the number of heactads in a patch). Estimates from patches with low numbers of hectads

238   were more variable. This heterogeneity creates an issue for ordinary least squares regression

239   and was addressed by using weighted regression: based on the variance in a patch size of n

240   hectads being s^2/n, where s^2 is the variance of species richness across all hectads in a habitat

241   group. The relative influences of competing models using combinations of the three predictor

242   variables (patch size, average coastline length of hectads in patch and total records in patch)

243   were also compared using AIC$_c$ values from competing linear regression models.

244

245   The influence of patch size on species identity was estimated using the matrix of Simpson's

246   dissimilarities for each habitat type. The null hypothesis here is that hectads drawn from

247   patches of similar sizes will be more similar than hectads from differently sized patches. This

248   was tested using the RELATE test within the PRIMER package, which calculates the rank

249   correlation between the matrix of dissimilarities and a distance matrix of difference in patch

250   size, using a randomization equivalent to a Mantel test to evaluate the significance of the

251   observed correlation (Clarke & Gorley, 2006).

252

253   The presence of edge effects on isolated hectads can also be tested by examining the structure

254   in the Simpson's dissimilarity matrix. Under the null hypothesis of no edge effects, the

255   average dissimilarity between a hectad and all hectads not in the same habitat group should

256   not change when comparing means from isolated hectads with means from hectads

257   contiguous with at least one hectad of the same habitat group. If the species composition in

258 isolated hectads is influenced by the surrounding habitat, then isolated hectads should be

259 more similar to hectads from other habitat groups than is the case for hectads from larger

260 patches.

261

262 **RESULTS**

263 The relationship between group number in the cluster analysis and explanatory power (r^2)

264 rose to an asymptote, but the profile contained jumps, with a pronounced plateau (Fig. 2).

265 The difference between the observed r^2 and the average profile from resampling also reached

266 a plateau, indicating that much of the pattern in the data could be explained by relatively few

267 groups. The most informative division was therefore taken to occur at 15 clusters, the

268 inflection point in the profiles.

269

270 With 15 clusters providing a parsimonious description of structure in the dataset, the three

271 largest identified clusters contained 94% of the 598 hectads with data. These three groups

272 were used to examine patch effects after identifying contiguous hectads with the same cluster

273 type. Although cluster members were found all around the coastline of Great Britain (Fig. 3),

274 there appeared to be some general associations with broad-scale habitat conditions. Hectads

275 in group A ($n = 358$) were generally found on open coasts and in positions consistent with the

276 likely presence of at least some rocky shore (including what Eurosion classed as

277 'conglomerates'). Group B (130 hectads) was concentrated around sheltered areas,

278 particularly estuarine areas like the Wash in the east of England, the Solent on the south coast

279 and the Solway Firth. The 73 hectads of group C seemed to be associated with predominantly

280 sedimentary shores in open coast areas. A cross referencing of hectads in separate clusters

281 with the nearest Eurosion category showed strong associations (G-test of association, $G_6 =$

282 338, $P < 0.001$, clusters not random across Eurosion habitat types).

283

284 The total species lists in the three largest groups were overlapping in content, with an average

285 intergroup Simpson's dissimilarity of 6%. Within the small number of species exclusive to

286 each group, there was some evidence to support the broad-scale environmental associations

287 suggested from Fig. 3. For example, the saltmarsh and seagrass specialists *Assiminea*

288 *grayana* and *Haminoea navicula* were found exclusively in group B. Relative frequencies of

289 species in the separate groups were also suggestive of a coarse separation into dominant shore

290 types: characteristic rocky shore species such as *Patella vulgata*, *Nucella lapillus*,

291 *Melarhaphe neritoides* and *Gibbula umbilicalis* were more than four times more likely to be

292 found in group A than in the other two groups.

293

294 Pairs of hectads within the same habitat group became more dissimilar with distance (Fig. 4).

295 In contrast, distances between hectads within a patch were relatively small, reflecting the

296 sizes of patches overall. This meant that the average beta dissimilarity between hectads was

297 greater than the dissimilarities within patches. Observed species lists in patches are therefore

298 accumulated from less distinct species lists than is the case for random allocations: as patches

299 are made up of neighbouring hectads more similar than the average for the coastline as a

300 whole. This phenomenon was reflected by larger habitat patches having fewer species than

301 would be expected on the basis of random allocation of hectads to patches (Fig. 5, Table 1).

302 The model with an interaction between patch size and habitat type had an evidence ratio

303 suggesting that it was more than twice as likely as more simple models. The relative decline

304 in accumulated species was greatest in habitat B, associated with estuarine habitats. This

305 grouping also had a standardized species number above one for single hectad patches:

306 indicating that single hectad patches were richer than might be expected by chance (mean

307 standardized species richness for single hectad patches = 0.65, SE 0.288). By comparison,

308   single hectad patches of habitat C had close to the expected number of species (mean

309   standardized richness -0.09, SE 0.1176). Single hectad patches of habitat A had fewer species

310   than would be expected from random selection of single hectads (mean score -0.42, SE

311   0.173).

312

313   Unsurprisingly, the proxy for collection effort, number of records, was a consistent predictor

314   of the average species richness hectad^{-1} in different patches (Fig. 6). Patch size was also

315   supported as a predictor for species density, although the effects were not consistent in

316   different habitat groups (Table 2). For group A, the evidence ratio suggests that the optimum

317   model was over three times as likely as the next best alternative. For this habitat, consistent

318   with rocky shore dominated areas, species density increased with patch size (slope 0.00254,

319   SE 0.000781). In contrast, species density declined with patch size in habitat group B

320   (estuarine areas). The optimum model for habitat group B had overwhelming support

321   compared to competing models and included all three predictor variables. This habitat group

322   therefore had evidence for an additional effect of coastline length. Species density was higher

323   in more convoluted estuarine areas. The final habitat group had less support for an optimum

324   model, although the effect of species record number was still positive for species density. The

325   weakly supported alternative model (w_iAIC$_c$ = 0.298) had a negative relationship between

326   patch size and species density, although the estimated error around the slope was relatively

327   high (habitat C, model averaged slope for patch size = -0.03, SE 0.023).

328

329   The dissimilarity between hectads did not seem to be a function of the relative patch size for

330   habitat A (RELATE test, correlation between dissimilarity matrices = 0.001, $P > 0.05$). In

331   contrast, greater differences in patch size were related to the degree of difference in species

332   composition within habitat B (correlation 0.039, $P < 0.05$) and habitat C (correlation = 0.084,

333 *P* < 0.05). Aside from intra habitat changes in dissimilarity, inter habitat dissimilarity was

334 also affected by patch size for two habitat groups (Table 3). Isolated hectads of both habitat

335 groups B and C were more similar to hectads from other groups when compared to the means

336 from larger patches. In contrast, isolated hectads of habitat A were no less dissimilar to non-

337 A habitat than larger patches.

338

339 **DISCUSSION**

340 There were habitat-specific differences in the way species accumulated in patches of different

341 size and in the influence of patch size on species richness hectad^{-1}. In the case of habitat

342 group A (rocky shore dominated), the increase in species density with patch area in larger

343 patches of group A habitat is an effect consistent with patterns seen in island biogeography.

344 An island effect is also suggested by the pattern for single hectad fragments of habitat A to

345 have fewer species than expected from a random selection of hectads. Habitat B had the

346 opposite pattern, relatively species rich single hectads, with a decline in species density in

347 larger patches. In contrast, there was less evidence for patch size effects on species richness

348 in the third habitat grouping (associated with sedimentary shores in open coast areas).

349

350 It is not clear why the habitat group consistent with rocky shores had an island

351 biogeographical effect of increasing species density in hectads from larger patches. The

352 inference from island biogeography is that species extinction is lower and/or immigration to

353 hectads is higher in larger patches. Immigration of molluscan species to areas of newly

354 established artificial hard shores far smaller than hectads seems relatively rapid (Dethier *et al.*,

355 2003; Krone *et al.*, 2013). Other studies, however, suggest that recolonization can take

356 decades for species with direct development (Johnson *et al.,* 2008). The converse of a

357 positive effect of patch size on the supply of colonists to individual hectads would be an

358   increase in extinction in small fragments of rocky shore. For example, if being surrounded by

359   sedimentary areas increases stress on rocky shores (e.g., by sedimentation or scouring,

360   Airoldi, 2003), this may cause greater local extinction rates with lower associated mollusc

361   diversities.

362

363   Both greater immigration to larger patches and greater loss of species in isolated hectads can

364   affect the species density–patch size relationship in the same way: it is therefore difficult to

365   separate these potential effects in the current study. Little is known about the extinction–

366   colonization dynamics of intertidal species at the scale of hectads. Considerable turnover has

367   been observed in areas of 4 m^2 monitored over a decade (Dye, 1998); for reasons of

368   tractability, most monitoring occurs at a similar scale. If larger patches reflect an increased

369   potential for source populations to supply colonists for recovery of local extinctions, this may

370   lead to greater local species densities. As the habitats are large relative to the movement

371   capacity of intertidal molluscs, a link between habitat extent and hectad-scale extinction

372   colonization dynamics would require a metapopulation effect with local populations linked

373   by larval dispersal or rafting. Repeated surveys of areas with different habitat extents could

374   test a recolonization rate and local extinction rate hypotheses, but this would be a challenging

375   project and not one that appears to have been attempted as yet.

376

377   The lower species richness hectad^{-1} in larger patches of estuarine habitat (group B) is not

378   surprising given the general tendency for estuarine habitats to be species poor (Attrill, 2002).

379   However, this alone does not explain why a landscape effect similar to rocky shores does not

380   seem to be present in habitat B. The positive influence of average coastline length implies

381   that more convoluted coastlines promote species richness. A more convoluted coastline could

382   promote species richness hectad^{-1} by an effect of habitat area, but this is not consistent with

383   the decline in species density in larger patches of habitat B. It therefore seems more likely

384   that the positive effect of coastline length reflects greater habitat heterogeneity. As single

385   hectads of habitat B had higher species richness than expected by chance alone (Fig. 5), this

386   implies an edge effect of enrichment from surrounding, non-estuarine, habitat or that the

387   isolated fragments have a greater chance of including diverse habitat types, with larger

388   patches being more homogenous. Such edge effects are supported by the observation that

389   isolated hectads of habitat B are more similar to the surrounding habitat than is the case for

390   hectads from larger patches (Table 3).

391

392   Habitat C seemed to have few influences of patch size on species richness. The decline in

393   accumulated species in larger patches is consistent with patches undersampling the available

394   diversity among hectads in the dataset, as occurred for the other habitat groups. Similar to

395   Habitat B, there was some suggestion for enrichment from surrounding habitat in isolated

396   hectads of Habitat C, along with some patch size related changes in assemblage composition.

397

398   A distinction that may explain the differences between predominantly hard (group A) and

399   soft habitats (groups B and C) is that relatively more species in soft habitats are also found

400   subtidally. For example, the sediment dwelling genera *Abra*, *Cerastoderma* and *Mya* are

401   given as characteristic components of both littoral and subtidal biotopes in the marine habitat

402   classification for Britain and Ireland (Connor *et al.,* 2004). In contrast, *Littorina* species

403   occurred more frequently in habitat A than any other habitat group, are listed as components

404   of over 50 interdidal biotopes, but only mentioned in one uncommon subtidal biotope

405   (Connor *et al.,* 2004). With additional source areas available, patch size may not be such a

406   good proxy for potential source populations in sedimentary habitats as it is in rocky habitats.

407

408   The theory of island biogeography relies on changes in colonization–extinction dynamics

409   related to island size. Colonization and extinction are also related to life history traits, with

410   the presence or duration of a pelagic dispersal stage potentially influencing molluscan species

411   distributions at a number of scales (Johnson *et al.,* 2001). The absence of a larval stage

412   generally restricts the estimated average dispersal distance of marine species (Kinlan and

413   Gaines, 2003). Under the inference that direct developers are poor dispersers, one might

414   expect this group of species to benefit more from the presence of alternative source

415   populations in a larger habitat patch. This idea was examined by calculating the average

416   patch size where each species was found and then comparing means between the different

417   dispersal modes. If large patches favour direct developers, this group should have a higher

418   average patch size than planktonic dispersers. The result of this comparison was not

419   significant (e.g., average patch size where direct developers found in habitat A = 28.6 hectads

420   (SE 1.31), n =54; equivalent values for planktonic dispersers: mean 26.4 hectads (SE 0.69), n

421   = 214). It is difficult, however, to interpret the lack of a difference between dispersal modes

422   in the face of examples where direct developing species have been shown to reach isolated

423   habitat patches (Johannesson, 1988; O'Foighil, 1989); observations that undermine the

424   assumption behind a simple distinction in colonization range between dispersal modes. The

425   RELATE test makes a further point with respect to the differences between patch sizes: there

426   was not a clear pattern for different assemblages on different sized patches of habitat A.

427   Some influence of patch size on species turnover was evident in habitat types B and C. This

428   may reflect the influences of surrounding habitat on patches of different sizes, particularly the

429   edge effects proposed for habitats B and C earlier.

430

431   As emphasized by Giladi *et al.* (2014), the different techniques of species density and species

432   accumulation applied in the current study emphasize separate mechanisms affecting species

433   richness. The patterns are also likely to be grain-size dependent. Experience of resampling

434   species occurrence grids at different scales suggests that measures of turnover decrease as

435   grain size increases (Lennon *et al.,* 2001). By collating the information at larger scales, the

436   turnover of species at smaller scales is lost, in the same way that widely spaced temporal

437   sampling can miss species turnover (the residency effect, Burns, 2014). If the data were

438   available to subdivide hectads, larger levels of turnover would therefore be expected. This

439   might be expected to lead to greater definition of habitat classes and a wider diversity of

440   landscape effects ranging from none to strong effects depending on target habitat and context.

441

442   It is possible to move to analyses at larger grain scales. As predicted, this decreases the

443   average turnover among locations (e.g., mean Simpson's dissimilarity declines from 0.47

444   among hectads to 0.33 when using 50 km $\times$ 50 km cells). Lower discrimination between

445   locations results in the definition of fewer groups that explain less of the observed structure

446   (compare 15 groups with a difference of 0.45% between observed and resampled r^2 in Fig. 2

447   to a difference of 0.19% for five groups with 50 km $\times$ 50 km cells, results not shown). A

448   consequence of moving grain size is that different habitats are identified. This restricts the

449   comparisons that can be done across scales. For example, Habitat C is split almost evenly

450   across the two largest groupings of 50 km $\times$ 50 km cells.

451

452   The effect of patch size on hard-shore communities suggests that increased use of shore

453   armouring and artificial structures will affect biogeographical patterns by increasing hard

454   shore habitat. One of the concerns about novel structures in the sea is that this will facilitate

455   the establishment of invasive species (Mineur *et al.,* 2012). The inferred island

456   biogeographical effects from species density are consistent with this hypothesis, although the

457   pattern is likely to be a positive relationship between native and introduced species density

458 (Mineur *et al.,* 2008) unless the novel structures lead to a greater degree of habitat

459 homogeneity at the patch scale.

460

461 For conservation planning, the results suggest that reserve spacing and sizes should be

462 considered differently for the different habitat groups. Soft sediment areas maintain species

463 richness in small fragments, so relatively small protected areas (1 hectad) may be functional,

464 with the highest diversity achieved by spacing around the coastline. In contrast, the more

465 rocky shore dominated areas have landscape effects, suggesting that landscape context should

466 also be considered when selecting areas for protection.

467

468 Overall, the results suggest that the presence of landscape and edge effects depends on the

469 type of habitat defined at the scale of analyses. The patch size of rocky habitat appears to

470 promote mollusc species density, possibly by increasing the pool of potential local source

471 populations and/or by reducing local extinction rates. This does not appear to result in a

472 different assemblage in larger patches of rocky habitat, so the majority of associated species

473 appear to benefit. In contrast, species density in soft sediments appears to benefit most from

474 heterogeneity of habitats in adjoining hectads. Intertidal molluscs associated with rocky and

475 sedimentary habitats have different relationships to potential source habitat. The results are

476 consistent with the observation of stronger island effects when species have a higher degree

477 of specialization on the focal habitat (cf., Cook *et al*., 2006, Lövei *et al*., 2006). It is likely

478 that other intertidal groups will have different responses, reflecting other relationships with

479 potential source habitats, including variation in the fidelity of species to particular habitats.

Biosketch

Mark Johnson is a marine ecologist with interests in the spatial ecology of benthic and pelagic systems.

Author contributions: M.J., C.A.M. and A.L.A conceived the project. A.J.B. collated the data and was involved with the other authors in discussions over the patterns within the data. M.J. carried out the final analyses and wrote the first draft with subsequent contributions from the other authors.

Editor: Michael Dawson

610   **Table 1.** Ranking of alternative models for the change in standardized intertidal molluscan

611   species richness in patches of different sizes, with habitat type considered as a categorical

612   variable. Records were extracted in 2008 for the coastline of Great Britain with habitats

613   defined by clustering (distributions shown in Fig. 3). Variables shown as Patch: log number

614   of hectads in patch and Habitat: Habitat group. The small sample corrected AIC (AIC_c) was

615   used to compare models. ΔAIC_c is the difference between the model with the lowest AIC_c

616   and other models, $w_i AIC_c$ are Akaike weights used to compare the support for different

617   models.

618

Predictor variables in model	r_{adj}^2 (%)	AIC_c	ΔAIC_c	$w_i AIC_c$
Habitat, Patch, Habitat × Patch	15	445.2	0.00	0.585
Habitat, Patch	13	447.1	1.88	0.229
Patch	11	447.5	2.30	0.186
Habitat	4.4	458.3	13.16	0.001

619

620 **Table 2.** Evaluation of alternative models for the average intertidal molluscan species

621 richness hectad^{-1} in patches of different size around the coast of Great Britain. Predictor

622 variables are the average coastline length of hectads in a patch (coastline), the log of the total

623 number of species records in the patch (Records) and the number of hectads in the patch

624 (Patch). The small sample corrected AIC (AIC$_c$) was used to compare models. ΔAIC$_c$ is the

625 difference between the model with the lowest AIC$_c$ and other models, w_iAIC$_c$ are Akaike

626 weights used to compare the support for different models. Colinearity of predictor variables

627 was minimal, variance inflation factors (VIFs) were below 1.4

628 a) Habitat group A

Coastline	Records	Patch	r_{adj}^2 (%)	AIC$_c$	ΔAIC$_c$	w_iAIC$_c$
	X	X	70	-14.4	0.00	0.737
X	X	X	70	-12.1	2.31	0.233
X	X		66	-6.8	7.63	0.016
	X		65	-6.5	7.94	0.014
		X	15	47.9	62.29	0.000
X		X	14	50.2	64.59	0.000
X			2	56.8	71.24	0.000

629

630 b) Habitat group B

Coastline	Records	Patch	r_{adj}^2 (%)	AIC$_c$	ΔAIC$_c$	w_iAIC$_c$
X	X	X	81	-1.6	0.00	0.946
	X	X	78	5.1	6.76	0.032

633

634   **Table 3.** Mean hectad dissimilarities between each of the three main habitat groups defined

635   for intertidal molluscs and all hectads not in the focal habitat group. Records were collated

636   for hectads around the coast of Great Britain, as described in the text. Dissimilarities were

637   calculated with the Simpson's index, where larger values indicate greater species turnover

638   bwteen the hectads being compared. Means were calculated for single hectad patches and for

639   all larger patches of the same habitat. Differences between means within a habitat were

640   examined with t-tests (equal variances not assumed).

641
642

Habitat group	Mean dissimilarity between habitat group and hectads not in same group (SE)		t value (df)	p
	Isolated hectads	Patches with more than one hectad		
A	0.57 (0.024)	0.58 (0.006)	0.32 (26)	>0.05
B	0.51 (0.034)	0.62 (0.016)	3.03 (33)	<0.01
C	0.48 (0.018)	0.57 (0.023)	3.04 (60)	<0.01

643

644

645 **Figure legends**

646 **Figure 1.** Simplified shoreline types for Great Britain derived from the Eurosion dataset

647 (http://www.eurosion.org/) hosted by the European Environment Agency. For simplicity, the

648 20 morpho-sedimentological codes of Eurosion have been amalgamated into rocky shores

649 (including artificial substrate), sedimentary shores (beaches), estuarine-type habitats and

650 conglomerates/cliffs with rock and sediment on the shore. The latter category is intermediate

651 between rocky and sedimentary shore. Locations mentioned in the text are labelled.

652

653 **Figure 2.** Degree of variation accounted for (as r^2) as a function of the number of clusters

654 defined in the hectad data for intertidal molluscs around the coast of Great Britain. The

655 observed pattern is derived from clusters defined by UWPGA averaging of the matrix of

656 dissimilarities among hectads. The random group allocation line is generated by permuting

657 the group labels randomly across hectads (mean of 100 randomizations for each group

658 number). The dotted line for observed-random indicates the information content over and

659 above the expected increase in r^2 with group number. Profiles show a sharp inflection at 15

660 groups, which was taken to give a parsimonious description of structure in the data.

661

662 **Figure 3.** Distribution of hectads allocated to the three most common habitat groups (A, B, C)

663 defined by clustering of intertidal mollusc data for Great Britain. The three groups contain 94%

664 of the 598 hectads with data and were defined in the most informative grouping based on the

665 proportion of variance explained (r^2).

666

667 **Figure 4.** Comparison between (a) the distribution of separation distances between hectads

668 within patches and (b) the average turnover of mollusc species between hectads separated by

669 different distances (as mean Simpson's dissimilarity, error bars SE). The majority of within-

670   patch separations are less than 25 km, at which point turnover is lower than the asymptotic

671   value. Data are shown for habitat group A only, but the patterns are similar in groups B and C.

672

673   **Figure 5.** Relationship between patch size and the accumulated number of intertidal mollusc

674   species found in the patch. The species list for each patch is expressed as a standardized score

675   with reference to the mean and standard deviation from a random allocation (within each

676   habitat group) of hectads to patches. If species richness is unaffected by landscape-related

677   processes, the data are expected to have a mean of 0 and no slope. The separate lines

678   represent the patch size $\times$ habitat group interaction found in the best supported model (r_{adj}^2

679   15%).

680

681   **Figure 6**. Residual variation in mollusc species density (species hectad^{-1}) as a function of

682   predictor variables in the optimum model (identified using AIC$_c$ in a multiple regression

683   analysis). Plots separate the influence of variables controlled for the influence of other

684   predictors. Rows in the figure show the patterns for different habitats, distinguished as open

685   circles (habitat A), filled triangles (habitat B) and shaded squares (habitat C). Each column

686   relates to a separate predictor variable. As only the variables contained in the optimum model

687   for each habitat are shown, gaps in the figure indicate where a no contribution was estimated

688   for a predictor of variation in mollusc species density for a particular habitat.
